# Nonmonotone Submodular Maximization via a Structural Continuous Greedy Algorithm 

Moran Feldman*, Joseph (Seffi) Naor*夫, and Roy Schwartz<br>Computer Science Dept., Technion, Haifa, Israel<br>\{moranfe, naor,schwartz\}@cs.technion.ac.il

#### Abstract

Consider a suboptimal solution $S$ for a maximization problem. Suppose $S$ 's value is small compared to an optimal solution $O P T$ to the problem, yet $S$ is structurally similar to $O P T$. A natural question in this setting is whether there is a way of improving $S$ based solely on this information. In this paper we introduce the Structural Continuous Greedy Algorithm, answering this question affirmatively in the setting of the Nonmonotone Submodular Maximization Problem. We improve on the best approximation factor known for this problem. In the Nonmonotone Submodular Maximization Problem we are given a non-negative submodular function $f$, and the objective is to find a subset maximizing $f$. Our method yields an 0.42 -approximation for this problem, improving on the current best approximation factor of 0.41 given by Gharan and Vondrák [5]. On the other hand, Feige et al. [4] showed a lower bound of 0.5 for this problem.

## 1 Introduction

Consider a situation where one has a suboptimal solution $S$ for a maximization problem. The most natural measure for the quality of $S$ is its value with respect to the objective function. However, an additional measure is the structural similarity of $S$ to an optimal solution $O P T$ of the problem. We are interested in the relation between these two measures. Suppose $S$ is structurally similar to $O P T$, yet its value is small. We call problems in which such sets exist uncorrelated objective-structure problems. For such problems it is possible for an algorithm to produce a solution which is structurally very similar to $O P T$, and yet is a poor approximation with respect to values. For example, in the Max Cut problem, suppose the input is a star. If we put all vertices on one side of the cut, we get a solution of value 0 which is only different from $O P T$ in one vertex.

For every uncorrelated objective-structure problem $\mathcal{P}$, a natural question is whether there is an efficient algorithm that, given a solution $S$ structurally similar to $O P T$, produces a solution $S^{\prime}$ of large value; i.e., we look for an algorithm trading structural similarity to $O P T$ for value. If we find such an algorithm for

[^0]problem $\mathcal{P}$, then we can improve approximation algorithms for $\mathcal{P}$ which produce (directly, or indirectly) solutions that are structurally similar to $O P T$.

In this paper we suggest the structural continuous greedy algorithm trading structural similarity to $O P T$ for value in the context of the Nonmonotone Submodular Maximization Problem (NSM). Given a ground set $\mathcal{E}$, a function $f: 2^{\mathcal{E}} \rightarrow \mathbb{R}$ is called submodular if for every $A, B \subseteq \mathcal{E}, f(A)+f(B) \geq$ $f(A \cup B)+f(A \cap B)$. An instance of NSM consists of a non-negative submodular function $f$, and its objective is to find a subset of $\mathcal{E}$ maximizing $f$. An explicit representation of $f$ might be exponential in the size of $\mathcal{E}$. Hence, we assume the value oracle model in which the algorithm has access to an oracle that given a set $S$ returns $f(S)$. This model is probably the most standard one, and is common throughout the literature.

To see why NSM is indeed an uncorrelated objective-structure problem, observe the following example. Consider the groundset $\mathcal{E}=[n] \times\{a, b\}$, and the submodular function: $f(S)=\sum_{i=1}^{n} g(S \cap\{(i, a),(i, b)\})$, where $g$ is an indicator function for the event that its argument is a set of size 1 . The set $\mathcal{E}^{\prime}=[n / 2] \times\{a, b\}$ has $f\left(\mathcal{E}^{\prime}\right)=0$ although it contains half of the elements of every optimal solution.

In the next section we describe the structural continuous greedy algorithm. We need a few well known terms, which we define here for completeness. Given a function $f$, if $f(\varnothing)=0$ we say that $f$ is normalized, and if for every $A \subseteq$ $B \subseteq \mathcal{E}, f(A) \leq f(B)$ (respectively, $f(A) \geq f(B)$ ), we say that $f$ is monotone (respectively, down monotone). Also, we use the notation of $O P T$ throughout the article to denote an optimal solution to the problem in question. If there are multiple optimal solutions, $O P T$ denotes an arbitrary fixed one.

### 1.1 The Structural Continuous Greedy Algorithm

Let us formally define the structural similarity of a set $S$ to $O P T$. One natural definition is $f(S \cap O P T)$. This definition makes sense for a monotone $f$. However, when $f$ may be nonmonotone, we need a definition that also captures structural similarity due to elements outside of $O P T$ missing also from $S$. Thus, we define the structural similarity of a set $S$ to $O P T$ as $f(S \cap O P T)+f(S \cup O P T) .{ }^{1}$

Consider a set $S$. Removing all elements of $S-O P T$ changes the value of this set to $f(S \cap O P T)$; hence, if $f(S \cap O P T)>f(S)$, removing all the elements of $S-O P T$ from $S$ increases the objective function. By submodularity, the last property also implies that there is at least one element in $S-O P T$ whose removal from $S$ increases its value. Putting it all together, $f(S \cap O P T)>f(S)$ implies the existence of an element $e \in S-O P T$ such that $f(S-\{e\})>f(S)$. Similarly, $f(S \cup O P T)>f(S)$ implies the existence of an element $e \in O P T-S$ such that $f(S \cup\{e\})>f(S)$. We can now relate our observations to the definition of structural similarity: if $f(S \cap O P T)+f(S \cup O P T)>2 f(S)$, then the value of $S$ can be improved by adding or removing a single element from it.

[^1]The last conclusion seems to suggest that given a set $S$ which is structurally similar to $O P T$, and yet has a low value, $S$ can be improved using a local search algorithm seeking at every stage to improve $S$ by adding or removing a single element. However, as this algorithm adds and removes elements, the structural similarity to $O P T$ might decrease; and we do not know how to relate this decrease to the increase in $f(S)$. Therefore, although we can conclude that such a local search algorithm will improve $S$, it is not clear how to give any positive lower bound on this improvement.

To work around this difficulty, we propose the structural continuous greedy algorithm. This algorithm maintains a fractional set (i.e., a set in which every element appears independently with some probability). Initially, every element of the input set $S$ appears in the fractional set $S^{\prime}$ with probability 1, and every other element appears in it with probability 0 . In every iteration the probability of each element can be changed by a small $\delta$. The probability of an element is increased if doing so increases the expected value of the fractional set, assuming all other probabilities are unchanged; and decreased otherwise.

Using arguments similar to those above, we can lower bound the improvement in every iteration of the structural continuous greedy algorithm in terms of $\mathbb{E}\left[f\left(S^{\prime} \cap O P T\right)+f\left(S^{\prime} \cup O P T\right)-2 f\left(S^{\prime}\right)\right]$. Hence, as long as $S^{\prime}$ is structurally similar to $O P T$, in expectation, the structural continuous greedy is guaranteed to improve it by changing the probabilities of elements. Moreover, after $m$ iterations, the change in the structural similarity of $S^{\prime}$ to $O P T$ can be upper bounded using the following observation: every element of the original set $S$ appears in $S^{\prime}$ with probability at least $1-m \delta$, and every element outside of $S$ appears in $S^{\prime}$ with probability at most $m \delta$; which intuitively means that $S^{\prime}$ is quite similar (structurally) to $S$, and therefore, also to $O P T$.

The structural continuous greedy inherits much of its structure from an algorithm of Vondrák [16] called "continuous greedy"; however, the two algorithms are analyzed very differently. The roots of [16]'s continuous greedy algorithm can be traced back to Wolsey [18], who also gives an algorithm called "continuous greedy", although, the two "continuous greedy" algorithms share only vague general ideas. The continuous greedy algorithm of [16] starts with an empty set, and then only increases the probabilities of elements. This is fine since [16] deals with monotone submodular functions. On the other hand, the structural continuous greedy, introduced in this paper, works with nonmonotone functions, which requires both modifications of the algorithm and its analysis (with respect to the algorithm and analysis of [16]).

There are two differences between our structural continuous greedy algorithm, and the "continuous greedy" algorithm of [16]. First, the initial point of the structural continuous greedy algorithm is an arbitrary set, and second, it may both increase and decrease probabilities. Though these differences are quite minor, the analysis of the two algorithms is completely different. The continuous greedy of [16] constructs a solution starting with an empty set, and its analysis strongly uses the monotonicity of $f$ (which implies that increasing the probabilities of $O P T$ 's elements is always good). On the other hand, the struc-
tural continuous greedy improves existing sets, and its analysis is based on the structural similarity of the input to $O P T$.

### 1.2 Taking Advantage of the Structural Continuous Greedy

The structural continuous greedy algorithm can improve sets that are already structurally similar to $O P T$ (at the cost of possibly decreasing their structural similarity to $O P T$ ). However, it is not clear, at first glance, how this can be used to produce an approximation algorithm for NSM. In order to answer this question, we have to understand the details of the known algorithms for NSM.

The first constant factor approximation algorithms for NSM were given by Feige et al. [4]. The simplest algorithm they provide simply selects every element of the ground set with probability $1 / 2$. Feige et al. [4] showed that this simple algorithm already achieves a $1 / 4$-approximation. They also suggested a local search algorithm which basically starts with an arbitrary set and adds or removes single elements as long as this improves the value of the set. The output set of this algorithm is called locally optimal because it cannot be improved by adding or removing a single element. In [4], it is shown that any locally optimal set gives a $1 / 3$-approximation for NSM.

The problem with local search algorithms is that they tend to get "stuck" in local optima. One way to get around that is to add some noise to the system. For that purpose, [4] defines for every set $S$, a random set $R(S)$ containing every element of $S$ with probability $2 / 3$ and every other element with probability $1 / 3$ (in other words, to get $R(S)$, we start with $S$ and switch the state of every element, from being in $S$ to being outside of it or vice versa, with probability $1 / 3$ ). The local search algorithm now tries to find a set maximizing $\mathbb{E}[f(R(S))]$. Somewhat surprisingly, this randomized local search has an improved approximation ratio of $2 / 5$. Looking more carefully at the analysis of [4], it actually shows that if $S$ is a locally optimal set (with respect to the last algorithm), then:

$$
\mathbb{E}[f(R(S))]+\frac{f(\bar{S})}{9} \geq \frac{4 f(O P T)}{9}
$$

This inequality guarantees that the expected values of $\max \{f(\bar{S}), f(R(S))\}$ is at least $0.4 f(O P T)$. Now, observe that $f(S \cap O P T)+f(\bar{S} \cap O P T) \geq f(O P T)$, and $f(S \cup O P T)+f(\bar{S} \cup O P T) \geq f(O P T)$. This suggests a negative correlation between the structural similarity to $O P T$ of $S$ and $\bar{S}$ in the following sense: if one of them is structurally far from $O P T$, then the other one must be structurally close to $O P T$. Since $R(S)$ is basically $S$ with some noise, we also get a negative correlation between the structural similarity to $O P T$ of $R(S)$ and $\bar{S}$. Hence, if $R(S)$ has a low expected value, and it is too far from $O P T$ for the structural continuous greedy algorithm to improve it significantly, then $\bar{S}$ must have both: significant value and structural similarity to $O P T$; hence, running the structural continuous greedy algorithm on it is guaranteed to produce a good set.

Using the above observations, we can get a 0.413 -approximation, which already slightly improves on the state of the art algorithm of Gharan and Vondrack [5] that gives a 0.41-approximation (we defer details to a full version of this
paper). However, we can do better if we use the structural continuous greedy algorithm together with [5]'s algorithm, though the combination of these two techniques requires some work. The algorithm of [5] is a simulated annealing algorithm. It starts as a local search algorithm with a lot of noise (i.e., $R(S)$ is obtained from $S$ by adding or removing every element with high probability), and gradually decreases the noise level. Intuitively, starting with a lot of noise should help the algorithm avoid inferior local maxima.

Simulated annealing algorithms are common in practice, but they often turn out to be very hard to analyze. The analysis of [5] works as following. For some, relatively high, level of noise $p_{0}$, the algorithm is analyzed as a noisy local search algorithm, producing a lower bound on the value of the algorithm's solution at noise level $p_{0}$. Now, observe what happens as the algorithm reduces the noise level. In a locally optimal solution, infinitesimally increasing the probability of every element inside the solution, and decreasing the probability of every element outside of the solution, only improve the solution. This change in the probabilities is exactly equivalent to a reduction in the noise level. Hence, whenever the algorithm reduces the noise level, since the current solution is locally optimal (the algorithm does not reduce the noise level unless this is the case), the reduction in the noise level can only improve the solution.

The main observation of [5] is a way to show a positive lower bound on the improvement achieved when the noise is reduced. This lower bound is negatively correlated with $f(\bar{S})$, where $S$ is the current solution of the algorithm. This immediately implies that either the set $\bar{S}$ is good at some point, or the value of $S$ significantly increases as the noise level decreases. Together with the lower bound on the value of $S$ at noise level $p_{0}$, an approximation guarantee follows.

The above description does not give an obvious way to combine [5]'s algorithm with the structural continuous greedy. In order for the structural continuous greedy algorithm to be useful, we must find sets in the proof of [5]'s algorithm with the following properties.

- Structurally similar to $O P T$, at least when [5]'s algorithm behaves poorly.
- Has large value, again, at least when [5]'s algorithm behaves poorly.

If we find such a set, it can be improved using the structural continuous greedy algorithm, and then be used as an alternative solution. In other words, whenever the original algorithm behaves poorly, the structural continuous greedy produces a good alternative solution, which results in an improved approximation ratio.

To this end, we make the following observation. The bound, given by [5], on the improvement achieved when the noise is reduced is actually positively correlated with $f(S \cap O P T)+f(S \cup O P T)$. The negative correlation of the bound with $f(\bar{S})$ follows since, by submodularity, $f(\bar{S}) \geq f(O P T)-f(S \cap$ $O P T)-f(S \cup O P T)$. Another inequality that follows from $f$ 's submodularity is $f(\bar{S} \cap O P T)+f(\bar{S} \cup O P T) \geq 2 f(O P T)-f(S \cap O P T)-f(S \cup O P T)$. Hence, the lower bound is also negatively correlated with the structural similarity of $\bar{S}$ to $O P T$. In conclusion, if at some point the value of the algorithm's solution does not improve fast enough, then at that point $\bar{S}$ has two properties: it has a relatively high value and it is structurally similar to $O P T$. Therefore, applying
the structural continuous greedy algorithm to $\bar{S}$ is guaranteed to produce a good set. This is the intuition behind our 0.42 approximation for NSM.

We note that [4] showed that no algorithm making only a polynomial number of oracle queries gives better than $1 / 2$-approximation for NSM. This hardness result holds even when $f$ is symmetric, i.e., $f(S)=f(\mathcal{E}-S)$, in which case it is tight [4].

### 1.3 Related Work

It is well known that submodular functions can be minimized in polynomial time [14]. However, maximizing a submodular function turns out to be a much more difficult task. Maximization of nonnegative submodular functions generalizes well known NP-hard problems such as Max-Cut [6], and [4] proved it impossible to give better than 0.5 -approximation for it using a polynomial number of oracle queries. Related problems ask to maximize a nonnegative submodular function subject to various combinatorial constraints on the sets that we are allowed to choose $[7,11,12,17]$ or minimize a submodular function subject to such constraints $[15,8,9]$.

Another line of work deals with maximizing normalized monotone submodular functions, again, subject to various combinatorial constraints. A continuous greedy algorithm was given by Calinescu et al. [1] for maximizing a normalized monotone submodular function subject to a matroid constraint. Later, Lee et al. [12] gave a local search algorithm achieving $1 / p-\varepsilon$ approximation for maximizing such functions subject to intersection of $p$ matroids. Kulik et al. [10] showed a $1-1 / e-\varepsilon$ approximation algorithm for maximizing a normalized monotone submodular function subject to multiple knapsack constraints. Recently, Chekuri et al. [3], gave a nonmonotone counterpart of the continuous greedy algorithm of [16]. This result improves several nonmonotone submodular optimization problems. Some of the above results were generalized by Chekuri et al. [2], which gives a dependent rounding for various polytopes, including matroid and matroid-intersection polytops. The advantage of this rounding technique is that it guarantees strong concentration bounds for submodular functions.

Organization. Section 2 formally defines NSM and the notation we use. In addition, this section also states a few useful known technical lemmata. Section 3 describes the structural continuous greedy algorithm, and Section 4 shows how to combine this algorithm with the simulated annealing algorithm of [5].

## 2 Preliminaries

Formally, in NSM, we are given a nonnegative submodular function $f: 2^{\mathcal{E}} \rightarrow$ $\mathbb{R}^{+}$. The objective is to find a subset $S \subseteq \mathcal{E}$ maximizing $f(S)$. We denote the size of the ground set $\mathcal{E}$ by $n$. In all algorithms presented, we assume $n$ is larger than any given constant (if this is not the case, one can solve NSM optimally using an exhaustive search).

There are two well known extensions of a submodular function $f: 2^{\mathcal{E}} \rightarrow \mathbb{R}^{+}$ to the hypercube $[0,1]^{\mathcal{E}}$. The first one is $F(x):[0,1]^{\mathcal{E}} \rightarrow \mathbb{R}^{+}$, the multilinear extension introduced by [1]. For a given vector $z \in[0,1]^{\mathcal{E}}$, let $R(z)$ be a set containing every element $e \in E$ with probability $z_{e}$, independently. The multilinear extension of $f$ is defined as $F(z)=\mathbb{E}[R(z)]$. This extensions is called multilinear because it can also be written as follows:

$$
F(z)=\sum_{S \subseteq \mathcal{E}}\left(\prod_{e \in S} z_{e} \cdot \prod_{e \notin S}\left(1-z_{e}\right) \cdot f(S)\right)
$$

The other known extension of submodular functions is the Lovász extension introduced in [13]. Define $T_{\lambda}(z)$ to be the set of elements whose coordinate in $z$ is at least $\lambda$. The Lovász extension of a submodular function $f: 2^{\mathcal{E}} \rightarrow \mathbb{R}^{+}$is defined as $\hat{f}(z)=\int_{0}^{1} f\left(T_{\lambda}(z)\right) d \lambda$. This definition can also be interpreted in probabilistic terms as the expected value of $f$ over the set $T_{\lambda}(z)$, where $\lambda$ is uniformly selected from the range $[0,1]$. In this paper, the Lovász extension is used only to lower bound the multilinear extension. This is done using the following theorem.
Theorem 1 (Lemma A. 4 in [17]). Let $F(z)$ and $\hat{f}(z)$ be the multilinear and Lovász extensions of a submodular function $f$, respectively. Then, for every $z \in$ $[0,1]^{\mathcal{E}}, F(z) \geq \hat{f}(z)$.

We abuse notation, and write $F(z \cup S)$ to denote $\mathbb{E}[f(R(z) \cup S)]$, $F(z-S)$ to denote $\mathbb{E}[f(R(z)-S)]$ and so on. We also use the shorthand $\partial_{e} F(z)$ for $F(z \cup e)-F(z-e)$. The multilinear nature of $F$ yields the following useful observation which relates these notations.

Observation 1 Let $F(z)$ be the multilinear extension of a submodular function $f: 2^{\mathcal{E}} \rightarrow R^{+}$. Then, for every $e \in \mathcal{E}$,

$$
\partial_{e} F(z)=\frac{F(z \cup e)-F(z)}{1-z_{e}}=\frac{F(z)-F(z-e)}{z_{e}}
$$

assuming the denominators are not 0 .
The following lemma shows that the change in $F(z)$ induced by making a small modification to the coordinates of $z$ is almost equal to the sum of changes that would have resulted from modifying each coordinate independently. This kinds of lemmata are standard, however, we include its proof in Appendix A for completeness.
Lemma 1. Consider two vectors $z, z^{\prime} \in[0,1]^{\mathcal{E}}$ such that for every $e \in \mathcal{E}, \mid z_{e}-$ $z_{e}^{\prime} \mid \leq \delta$, for $\delta \leq n^{-3}$. Then, $F\left(z^{\prime}\right)-F(z) \geq \sum_{e \in \mathcal{E}}\left(z_{e}^{\prime}-z_{e}\right) \cdot \partial_{e} F(z)-O\left(n^{-1} \delta\right)$.

Given a set $S \subseteq E$ and a number $p \in[0.5,1]$, let $z^{p}(S)$ be a vector of $[0,1]^{\mathcal{E}}$, containing $p$ in the coordinate of every element of $S$, and $1-p$ in all other coordinates. Since the structural similarity of $S$ to $O P T$ is often used in our proofs, we denote it by $V(S)$, i.e., $V(S)=f(S \cap O P T)+f(S \cup O P T)$. For simplicity of the exposition we assume $f(O P T)=1$. This assumption removes some clattering from the mathematical calculations, and can be easily removed.

## 3 The Structural Continuous Greedy Algorithm

In this section we show the structural continuous greedy algorithm for NSM. The structural continuous greedy algorithm improves a set $S$ which has some structural resemblance to $O P T$ (at the cost of possibly making the set less structurally similar to $O P T$ ).

```
Structural Continuous Greedy for \(\operatorname{NSM}(f, S, \mathcal{E})\) :
1. Let \(\delta=n^{-3}\). Initialize \(t=0\) and \(z_{0}=1_{S}\).
2. While \(t<1\) do:
3. For every element \(e \in \mathcal{E}\) do:
    For every element \(e \in \mathcal{E}\) do:
If \(\partial_{e} F\left(z_{t}\right)>0,{ }^{a}\left(z_{t+1}\right)_{e}=\min \left\{1,\left(z_{t}\right)_{e}+\delta\right\}\).
        If \(\partial_{e} F\left(z_{t}\right)<0,\left(z_{t+1}\right)_{e}=\max \left\{0,\left(z_{t}\right)_{e}-\delta\right\}\).
    \(t \leftarrow t+\delta\)
7. Return \(R\left(z_{1}\right)\)
```

${ }^{a}$ The algorithm does not have access to $\partial_{e} F\left(z_{t}\right)$, however, it can approximate it up to any required accuracy by averaging independent random samples. This is a standard practice, and we omit details (e.g., see [1]). Taking the error induced by the random sampling into account effects our results, with high probability, only by a lower order term.

We prove in this section the following theorem.

Theorem 2. Assuming $V(S) \geq 2 f(S)$, the Structural Continuous Greedy Algorithm for NSM produces a solution of expected value at least

$$
\frac{V(S)}{4} \cdot\left[2-\ln \left[3-\frac{4 f(S)}{V(S)}\right]\right]-O\left(n^{-1}\right) .
$$

We define a few sets of elements that we will refer to. Let $\mathcal{E}_{t}^{0}$ (resp. $\mathcal{E}_{t}^{1}$ ) be the set of elements whose coordinates in $z_{t}$ are 0 (resp. 1), $\mathcal{E}_{t}^{+}$be the set $\left\{e \in \mathcal{E} \mid \partial_{e} F\left(z_{t}\right) \geq 0\right\}$, and $\mathcal{E}_{t}^{-}$be $\mathcal{E}-\mathcal{E}_{t}^{+}$.

The following lemma shows that there is a set of elements for which the gain achieved by changing the coordinate of each one of them independently (i.e., when we change one coordinate, we assume the others are kept unchanged) is significant.

Lemma 2. At every time $t, \sum_{e \in O P T \cap\left(\mathcal{E}_{t}^{+}-\mathcal{E}_{t}^{1}\right)} \partial_{e}\left(z_{t}\right)-\sum_{e \in \overline{O P T} \cap\left(\mathcal{E}_{t}^{-}-\mathcal{E}_{t}^{0}\right)} \partial_{e}\left(z_{t}\right) \geq$ $F\left(O P T \cap z_{t}\right)+F\left(O P T \cup z_{t}\right)-2 F\left(z_{t}\right)$.

Proof. Observe that:

$$
\sum_{e \in O P T \cap\left(\mathcal{E}_{t}^{-}-\mathcal{E}_{t}^{1}\right)} F\left(z_{t} \cup e\right)-F\left(z_{t}\right)=\sum_{e \in O P T \cap\left(\mathcal{E}_{t}^{-}-\mathcal{E}_{t}^{1}\right)}\left(1-\left(z_{t}\right)_{e}\right) \cdot \partial_{e} F\left(z_{t}\right) \leq 0
$$

Using this observation, we get:

$$
\begin{align*}
\sum_{e \in O P T \cap\left(\mathcal{E}_{t}^{+}-\mathcal{E}_{t}^{1}\right)} \partial_{e} F\left(z_{t}\right) & \geq \sum_{e \in O P T \cap\left(\mathcal{E}_{t}^{+}-\mathcal{E}_{t}^{1}\right)}\left(1-\left(z_{t}\right)_{e}\right) \cdot \partial_{e} F\left(z_{t}\right)  \tag{1}\\
& =\sum_{e \in O P T \cap\left(\mathcal{E}_{t}^{+}-\mathcal{E}_{t}^{1}\right)} F\left(z_{t} \cup e\right)-F\left(z_{t}\right) \\
& \geq \sum_{e \in O P T-\mathcal{E}_{t}^{1}} F\left(z_{t} \cup e\right)-F\left(z_{t}\right) \\
& \geq F\left(z_{t} \cup\left(O P T-\mathcal{E}_{t}^{1}\right)\right)-F\left(z_{t}\right)=F\left(z_{t} \cup O P T\right) .
\end{align*}
$$

Analogously, we can also get:

$$
\begin{equation*}
\sum_{e \in \overline{O P T} \cap\left(\mathcal{E}_{t}^{-}-\mathcal{E}_{t}^{0}\right)} \partial_{e} F\left(z_{t}\right) \leq F\left(z_{t}\right)-F\left(z_{t}-\overline{O P T}\right) \tag{2}
\end{equation*}
$$

The lemma now follows by combining (1) and (2).
Together with Lemma 1, Lemma 2 shows that there is a set of elements whose coordinates can be changed together to produce a significant improvement. The following lemma shows that the algorithm indeed finds such a set.

Lemma 3. $F\left(z_{t+\delta}\right)-F\left(z_{t}\right) \geq \delta\left[F\left(O P T \cap z_{t}\right)+F\left(O P T \cup z_{t}\right)-2 F\left(z_{t}\right)\right]-O\left(\delta n^{-1}\right)$.
Proof. The algorithm increases the coordinates of all elements in $\mathcal{E}_{t}^{+}-\mathcal{E}_{t}^{1}$ by $\delta$, and decreases the coordinates of all elements in $\mathcal{E}_{t}^{-}-\mathcal{E}_{t}^{0}$ by $\delta$. Hence, by Lemma 1,

$$
F\left(z_{t+\delta}\right)-F\left(z_{t}\right) \geq \delta \sum_{e \in \mathcal{E}_{t}^{+}-\mathcal{E}_{t}^{1}} \partial_{e} F(z)-\delta \sum_{e \in \mathcal{E}_{t}^{-}-\mathcal{E}_{t}^{0}} \partial_{e} F(z)-O\left(n^{-1} \delta\right)
$$

The lemma now follows by combining this inequality with Lemma 2.
The following lemma lower bounds the similarity of $R\left(z_{t}\right)$ to $O P T$ in terms of the similarity of the original set $S$ to $O P T$ and the time that passed so far.

Lemma 4. For every time $t$, the following two inequalities hold:
$-F\left(z_{t} \cap O P T\right) \geq(1-t) \cdot f(S \cap O P T)$.
$-F\left(z_{t} \cup O P T\right) \geq(1-t) \cdot f(S \cup O P T)$.
Proof. Clearly, for every element $e \in O P T, f(O P T) \geq f(O P T-e)$. By submodularity, this implies that $f$ is monotone on subsets of $O P T$. Observe that $f(X \cap O P T)$ is also a submodular function. Therefore, we can apply Theorem 1 to it, and get

$$
F\left(z_{t} \cap O P T\right) \geq \int_{0}^{1} f\left(T_{\lambda}\left(z_{t}\right) \cap O P T\right) d \lambda \geq \int_{0}^{1-t} f\left(T_{\lambda}\left(z_{t}\right) \cap O P T\right) d \lambda
$$

At time $t$, every element $e \in S$ must have $\left(z_{t}\right)_{e} \geq 1-t$, therefore, the set $T_{\lambda}\left(z_{t}\right)$ in the integrand must contain $S$. Hence, by plugging this observation into the previous inequality, and using the monotonicity of $f$ over subsets of $O P T$, we get

$$
F\left(z_{t} \cap O P T\right) \geq \int_{0}^{1-t} f(S \cap O P T) d \lambda=(1-t) \cdot f(S \cap O P T)
$$

The other inequality guaranteed by the lemma is proved analogously.
Plugging Lemma 4 into Lemma 3, we get the following lower bound on the improvement made by the algorithm at each step.

Corollary 1. $F\left(z_{t+\delta}\right)-F\left(z_{t}\right) \geq \delta\left[(1-t)[f(S \cap O P T)+f(S \cup O P T)]-2 F\left(z_{t}\right)\right]-$ $O\left(n^{-1} \delta\right)=\delta\left[(1-t) V(S)-2 F\left(z_{t}\right)\right]-O\left(n^{-1} \delta\right)$.

Let $g$ be the function which is the solution of the following recursive formula. $g(t+\delta)-g(t)=\delta[(1-t) V(S)-2 g(t)]$, with the boundary condition $g(0)=f(S)$. Lemmata 5 and 6 prove that it is sufficient to show that at some point $g(t) \geq X$ in order to prove $F\left(z_{1}\right) \geq X-O\left(n^{-1}\right)$.

Lemma 5. For evert time $t, F\left(z_{t}\right) \geq g(t)-O\left(n^{-1} t\right)$.
Proof. Let $c$ be the constant hiding behind the big $O$ in Corollary 1. We prove by induction that $F\left(z_{t}\right) \geq g(t)-c n^{-1} t$. For time $t=0$, the claim holds since $F\left(z_{0}\right)=f(S)=g(0)$. Assume the claim holds for some time $t$, let us prove it for time $t+\delta$ via Corollary 1.

$$
\begin{aligned}
F\left(z_{t+\delta}\right) & \geq(1-t) \delta V(S)+(1-2 \delta) F\left(z_{t}\right)-c n^{-1} \delta \\
& \geq(1-t) \delta V(S)+(1-2 \delta) g(t)-c n^{-1}(\delta+t)=g(t+\delta)-c n^{-1}(\delta+t)
\end{aligned}
$$

Lemma 6. For every time $t, F\left(z_{1}\right) \geq F\left(z_{t}\right)-O\left(n^{-1}\right)$.
Proof. The algorithm increases only coordinates of elements with a positive $\partial_{e} F\left(z_{t}\right)$, and decreases only coordinates of elements with a negative $\partial_{e} F\left(z_{t}\right)$. Hence, by Lemma 1, for every time $t, F\left(z_{t+\delta}\right) \geq F\left(z_{t}\right)-O\left(n^{-1} \delta\right)$. Hence, the value of $F\left(z_{t}\right)$ can decrease only by $O\left(n^{-1} \delta\right)$ in every time step. Since there are only $\delta^{-1}$ time steps, the lemma follows.

Let $h$ be the function $h(t)=\frac{3}{4} V(S) \cdot\left[1-\frac{2 t}{3}-e^{-2 t}\right]+e^{-2 t} \cdot f(S)$. Observe that $d h / d t=(1-t) V(S)-2 h(t)$. The next lemma shows that $h$ lower bounds $g$ (given some condition), and therefore, also lower bounds the value of the algorithm's solution.

Lemma 7. If for every $t^{\prime} \leq t, g\left(t^{\prime}\right) \leq 0.5(1-t) V(S)$, then $g(t) \geq h(t)$.
Proof. We prove the lemma by induction on $t$. For time $t=0$ the lemma follows from the definition of $h(0)$. Assume that the lemma holds for some time $t$, let
us prove it for time $t+\delta$. Let $t_{1}$ be the last time in the range $[t, t+\delta]$ in which $h\left(t_{1}\right) \leq g(t)$.

$$
\begin{aligned}
h(t+\delta) & =h\left(t_{1}\right)+\int_{t_{1}}^{t+\delta} h^{\prime}(\tau) d \tau=h\left(t_{1}\right)+\int_{t_{1}}^{t+\delta}((1-\tau) V(S)-2 h(\tau)) d \tau \\
& \leq g(t)+\int_{t_{1}}^{t+\delta}((1-t) V(S)-2 g(t)) d \tau \\
& =g(t)+\left(t+\delta-t_{1}\right)((1-t) V(S)-2 g(t)) \\
& \leq g(t)+\delta((1-t) V(S)-2 g(t))=g(t+\delta)
\end{aligned}
$$

Let $t^{*}=0.5 \ln \left[3-\frac{4 f(S)}{V(S)}\right]$. Notice that if $f(S \cup O P T)+f(S \cap O P T) \geq 2 f(S)$, then $\ell^{*} \in[0,0.5 \ln 3] \subseteq[0,1]$.

Lemma 8. Assuming $V(S) \geq 2 f(S), h\left(t^{*}\right)=0.25 V(S) \cdot\left[2-\ln \left[3-\frac{4 f(S)}{V(S)}\right]\right]$.
Proof.

$$
\begin{aligned}
& h\left(t^{*}\right)=h\left(0.5 \ln \left[3-\frac{4 f(S)}{V(S)}\right]\right) \\
& \quad=\frac{3}{4} V(S)\left[1-\frac{\ln \left[3-\frac{4 f(S)}{V(S)}\right]}{3}-\frac{V(S)}{3 V(S)-4 f(S)}\right]+f(S) \cdot \frac{V(S)}{3 V(S)-4 f(S)} \\
& \quad=\frac{3}{4} V(S)\left[1-\frac{\ln \left[3-\frac{4 f(S)}{V(S)}\right]}{3}\right]-\frac{V(S)}{4}=\frac{1}{4} V(S)\left[2-\ln \left[3-\frac{4 f(S)}{V(S)}\right]\right]
\end{aligned}
$$

We are now ready to prove Theorem 2.
Proof (of Theorem 2). First let us claim that somewhere $g$ gets the value:

$$
0.25 V(S) \cdot\left[2-\ln \left[3-\frac{4 f(S)}{V(S)}\right]\right]-O\left(n^{-3}\right)
$$

If the assumption of Lemma 7 does not hold for $t^{*}$, then $g$ gets, somewhere, the value:

$$
0.5\left(1-t^{*}\right) V(S)=0.5\left(1-0.5 \ln \left[3-\frac{4 f(S)}{V(S)}\right]\right) V(S)
$$

Which proves the claim. Therefore, we can safely assume that the assumption of Lemma 7 holds, which implies that $g$ gets value of at least $h\left(\delta \cdot\left\lfloor t^{*} / \delta\right\rfloor\right)$. In order to lower bound this value, we can use the observation that for every $t \in\left[0, t^{*}\right]$, $h^{\prime}(t) \leq 2$. Hence,

$$
h\left(\delta \cdot\left\lfloor t^{*} / \delta\right\rfloor\right) \geq h\left(t^{*}\right)-2 \delta \geq h\left(t^{*}\right)-2 n^{-3} .
$$

And the theorem now follows from Lemmata 5 and 6.

## 4 Simulated Annealing Algorithm

Given a set $S$, let us denote by $C(S)$ the random set resulting from running the structural continuous greedy algorithm on $S$. Consider the following algorithm.

```
Simulated Annealing Algorithm for NSM \((f, \mathcal{E})\) :
    Let \(d=0.752-\sqrt{2} /(1+\sqrt{2})\) and \(\delta=d\left\lceil n^{3} d\right\rceil^{-1} .{ }^{a}\)
    Initialize \(p=\sqrt{2} /(1+\sqrt{2})\) and \(A_{p}=\varnothing\).
    Repeat:
        Set \(B_{p} \leftarrow A_{p}\)
        While there exists a set \(S\) such that:
                            (i) \(\left|S \oplus B_{p}\right|=1\)
                            (ii) \(F\left(z^{p}(S)\right)>F\left(z^{p}\left(B_{t}\right)\right)\)
                Replace \(B_{p}\) with \(S\)
            Set \(A_{p+\delta} \leftarrow B_{p}\)
            Update \(p \leftarrow p+\delta\)
    Until \(p=0.752\).
10. Return the best set in \(\left\{R\left(z^{0.752}\left(B_{0.752}\right)\right)\right\} \cup\left\{\bar{B}_{p}, C\left(\bar{B}_{p}\right)\right\}_{p=\frac{\sqrt{2}}{1+\sqrt{2}}}^{0.752}\)
```

${ }^{a}$ Informally $\delta$ is the inverse of a number which is both at least $n^{3}$ and dividable by $d$.
Remark: As written the Simulated Annealing algorithm does not run in polynomial time for two reasons: the number of iterations that the algorithm makes might be exponential, and checking condition exactly $i i$ cannot be done in polynomial time using only value oracle access to $f$. However, both problems can be solved using standard means (see, e.g., $[12,1]$ ), at the cost of losing a lower order term in the approximation ratio. We omit the details.

Theorem 3. The Simulated Annealing Algorithm for NSM returns a solution whose expected value is at least 0.42 .

The proof of the theorem combines ideas from the proof of the simulated annealing algorithm of [5] with the new observations described in Section 1.2. Due to lack of space, this proof is differed to Appendix B.

## A Proof of Lemma 1

First, we need a few definitions. Let $A$ be the set of elements $e$ with $z_{e}^{\prime}>z_{e}$, and let $B$ be the set of elements with $z_{e}^{\prime}<z_{e}$. For the sake of the proof, we assume $R\left(z^{\prime}\right)$ is formed from $R(z)$ using the following process. Every element of $A-R(z)$ is added to a set $D$ with probability of $1-\left(1-z_{e}^{\prime}\right) /\left(1-z_{e}\right)$, and every element of $B \cap R(z)$ is added to $D$ with probability $1-z_{e}^{\prime} / z_{e}$. Then, $R\left(z^{\prime}\right)$ is defined as $R(z) \oplus D$. Observe that every element $e \in \mathcal{E}$ gets into $D$ with probability $\left|z_{e}-z_{e}^{\prime}\right| \leq \delta$, independently. We are now going to bound the value of $F\left(z^{\prime}\right)-F(z)=\mathbb{E}\left[f\left(R\left(z^{\prime}\right)\right)-f(R(z))\right]$, given various constraints on $D$.

Lemma 9. $\sum_{e \in \mathcal{E}}\left(z_{e}^{\prime}-z_{e}\right) \cdot \partial_{e} F(z) \leq \sum_{e \in \mathcal{E}} \operatorname{Pr}[D=\{e\}] \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z) \mid D=\right.$ $\{e\}]+2 n^{-1} \delta$.

Proof. Let $\mathcal{E}^{+}$be the set of elements from $\mathcal{E}$ which have $\left(z_{e}^{\prime}-z_{e}\right) \cdot \partial_{e} F(z) \geq 0$.
Observe that for every $e \in \mathcal{E}^{+}$,

$$
\begin{aligned}
\left(z_{e}^{\prime}-z_{e}\right) \cdot \partial_{e} F(z) & =\left|z_{e}^{\prime}-z_{e}\right| \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z) \mid D=\{e\}\right] \\
& =\frac{\operatorname{Pr}[D=\{e\}] \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z) \mid D=\{e\}\right]}{\prod_{e^{\prime} \in \mathcal{E}-e}\left(1-\left|z_{e^{\prime}}^{\prime}-z_{e^{\prime}}\right|\right)} \\
& \leq \frac{\operatorname{Pr}[D=\{e\}] \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z) \mid D=\{e\}\right]}{\prod_{e^{\prime} \in \mathcal{E}-e}(1-\delta)} \\
& =(1-\delta)^{1-|\mathcal{E}|} \cdot \operatorname{Pr}[D=\{e\}] \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z) \mid D=\{e\}\right] \\
& <(1-\delta)^{-n} \cdot \operatorname{Pr}[D=\{e\}] \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z) \mid D=\{e\}\right] .
\end{aligned}
$$

And the term, $(1-\delta)^{n}$ can be lower bounded as following.

$$
(1-\delta)^{n} \geq\left(1-n^{-3}\right)^{n} \geq \sqrt[n^{2}]{e^{-1}\left(1-n^{-3}\right)} \geq e^{-2 n^{-2}} \geq 1-2 n^{-2}
$$

Also, for every $e \in \mathcal{E}-\mathcal{E}^{+}$,

$$
\begin{aligned}
\left(z_{e}^{\prime}-z_{e}\right) \cdot \partial_{e} F(z) & =\left|z_{e}^{\prime}-z_{e}\right| \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z) \mid D=\{e\}\right] \\
& =\frac{\operatorname{Pr}[D=\{e\}] \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z) \mid D=\{e\}\right]}{\prod_{e^{\prime} \in \mathcal{E}-e}\left(1-\left|z_{e^{\prime}}^{\prime}-z_{e^{\prime}}\right|\right)} \\
& \leq \operatorname{Pr}[D=\{e\}] \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z) \mid D=\{e\}\right] .
\end{aligned}
$$

Combining everything, we get:

$$
\begin{aligned}
\sum_{e \in \mathcal{E}}\left(z_{e}^{\prime}-z_{e}\right) \cdot \partial_{e} F(z)-2 n^{-1} & \delta \leq \sum_{e \in \mathcal{E}}\left(z_{e}^{\prime}-z_{e}\right) \cdot \partial_{e} F(z)-\delta n\left(2 n^{-2}\right) \\
& \leq \sum_{e \in \mathcal{E}}\left[\left(z_{e}^{\prime}-z_{e}\right) \cdot \partial_{e} F(z)-2 n^{-2} \cdot\left|\left(z_{e}^{\prime}-z_{e}\right) \cdot \partial_{e} F(z)\right|\right] \\
& \leq \sum_{e \in \mathcal{E}} \operatorname{Pr}[D=\{e\}] \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z) \mid D=\{e\}\right]
\end{aligned}
$$

Lemma 10. $\mathbb{E}\left[F\left(z^{\prime}\right)-F\left(z_{t}\right) \mid D=\varnothing\right]=0$.
Proof. $D=\varnothing$ implies $R\left(z^{\prime}\right)=R(z)$.
Lemma 11. $\operatorname{Pr}[|D| \geq 2] \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z)| | D \mid \geq 2\right] \geq-2 n^{-1} \delta$.
Proof. Let us bound the probability that $|D| \geq 2$. Since every element enters into $D$ with probability at most $\delta \leq n^{-3}$ :

$$
\begin{aligned}
\operatorname{Pr}[|D| \geq 2] & \leq 1-(1-\delta)^{n}-n \cdot \delta \cdot(1-\delta)^{n-1} \leq 1-(1+n \delta) \cdot(1-\delta)^{n} \\
& \leq 1-(1+n \delta) \cdot e^{-n \delta} \cdot\left(1-n \delta^{2}\right) \leq 1-(1+n \delta)(1-n \delta)\left(1-n \delta^{2}\right) \\
& =1-\left(1-n^{2} \delta^{2}\right)\left(1-n \delta^{2}\right) \leq 2 n^{2} \delta^{2} \leq 2 n^{-1} \delta
\end{aligned}
$$

Therefore, we get:

$$
\operatorname{Pr}[|D| \geq 2] \cdot \mathbb{E}\left[F\left(z^{\prime}\right)-F(z)| | D \mid \geq 2\right] \geq-\operatorname{Pr}[|D| \geq 2] \geq-2 n^{-1} \delta
$$

Lemma 1 now follows immediately from the above lemmata and the law of total probability.

## B Proof of Theorem 3

In this section we assume for the sake of contradiction that the Theorem 3 is wrong, i.e., the expected value of the simulated annealing's solution is less than 0.42 .

Observation 2 For every time $p, F\left(z^{p}\left(B_{p}\right)\right) \geq F\left(z^{p}\left(A_{p}\right)\right)$.
Proof. Clearly, the value of $F\left(z^{p}\left(B_{p}\right)\right)$ never decreases. The observation now follows because the original value of $F\left(z^{p}\left(B_{p}\right)\right)$ is $F\left(z^{p}\left(A_{p}\right)\right)$.

Every set $B_{p}$ is a local optimum, i.e., there is no set $S \subseteq \mathcal{E}$ such that:
(i) $S$ is produced from $B_{p}$ by adding or removing a single element.
(ii) $F\left(z^{p}(S)\right)>F\left(z^{p}\left(B_{p}\right)\right)$ The following lemma applies to local optima.

Lemma 12 (Lemma 3.5 of [5]). Let $q \in[1 / 3,1 /(1+\sqrt{2})], p=1-q$ and let $S$ be a local optimum with respect to $F\left(z^{p}(S)\right)$. Let $\beta=f(\bar{S})$. Then,

$$
F\left(z^{p}(S)\right) \geq \frac{1}{2}\left(1-q^{2}\right)-q(1-2 q) \beta
$$

Corollary 2. For $p^{\prime}=\sqrt{2} /(1+\sqrt{2}), F\left(z^{p^{\prime}}\left(B_{p^{\prime}}\right)\right) \geq 0.384$.
Proof. By plugging $q=1-p^{\prime}=1 /(1+\sqrt{2})$ into Lemma 12, we get $F\left(z^{p^{\prime}}\left(B_{p^{\prime}}\right)\right) \geq$ $\sqrt{2}-1-(5 \sqrt{2}-7) f\left(\bar{B}_{p^{\prime}}\right)$. Since we assumed Theorem 3 is wrong, we get $f\left(\bar{B}_{p^{\prime}}\right)<$ 0.42 , and plugging this into the previous inequality yields

$$
F\left(z^{p^{\prime}}\left(B_{p^{\prime}}\right)\right) \geq \sqrt{2}-1-(5 \sqrt{2}-7) \cdot 0.42 \geq 0.384
$$

The next step is to show that every set $B_{p}$ is structurally similar to $O P T$.
Lemma 13. For $x \geq 2 y \geq 0$, the expression $E=x \cdot\left[2-\ln \left[3-\frac{4 y}{x}\right]\right]$ is an increasing function of $x$.

Proof. The derivative of $E$ by $x$ is

$$
\begin{aligned}
\frac{d E}{d x} & =\left[2-\ln \left[3-\frac{4 y}{x}\right]\right]-x \cdot \frac{\left[3-\frac{4 y}{x}\right]^{\prime}}{3-\frac{4 y}{x}} \\
& =\left[2-\ln \left[3-\frac{4 y}{x}\right]\right]-x \cdot \frac{\frac{4 y}{x^{2}}}{3-\frac{4 y}{x}}=2-\ln \left[3-\frac{4 y}{x}\right]-\frac{\frac{4 y}{x}}{3-\frac{4 y}{x}} .
\end{aligned}
$$

Replacing $4 y / x$ by $z$, and deriving the derivative by $z$, we get

$$
\left[2-\ln [3-z]-\frac{z}{3-z}\right]^{\prime}=\frac{1}{3-z}-\frac{(3-z)+z}{(3-z)^{2}}=\frac{3-z-3}{(3-z)^{2}} \leq 0
$$

Hence, increasing the value of $z$ decreases the derivative. Therefore,

$$
\frac{d E}{d x} \geq 2-\ln \left[3-\frac{4 y}{2 y}\right]-\frac{\frac{4 y}{2 y}}{3-\frac{4 y}{2 y}}=2-\ln [3-2]-\frac{2}{3-2}=2-\ln 1-2=0
$$

Lemma 14. For every $p, V\left(B_{p}\right) \geq 0.689$.
Proof. Since we assumed Theorem 3 is wrong, $f\left(\bar{B}_{p}\right), f\left(C\left(\bar{B}_{p}\right)\right)<0.42$. Assume, also, $f\left(B_{p} \cup O P T\right)+f\left(B_{p} \cap O P T\right)=V\left(B_{p}\right)<0.689$. Then:
$-f\left(\bar{B}_{p}\right) \geq 1-\left[f\left(B_{p} \cup O P T\right)+f\left(B_{p} \cap O P T\right)\right] \geq 0.311$.
$-V\left(\bar{B}_{p}\right)=f\left(\bar{B}_{p} \cup O P T\right)+f\left(\bar{B}_{p} \cap O P T\right) \geq 2-\left[f\left(B_{p} \cup O P T\right)+f\left(B_{p} \cap O P T\right)\right] \geq$ 1.311 .

We know $2 f\left(\bar{B}_{p}\right) \leq 0.84 \leq 1.311$, hence, we can use Theorem 2 and Lemma 13.

$$
\begin{aligned}
C\left(\bar{B}_{p}\right) & \geq 0.25 V\left(\bar{B}_{p}\right) \cdot\left[2-\ln \left[3-\frac{4 f\left(\bar{B}_{p}\right)}{V\left(\bar{B}_{p}\right)}\right]\right]-O\left(n^{-1}\right) \\
& \geq 0.25 \cdot 1.311 \cdot\left[2-\ln \left[3-\frac{4 \cdot 0.311}{1.311}\right]\right]-O\left(n^{-1}\right) \geq 0.42
\end{aligned}
$$

Which contradicts the assumptions that Theorem 3 is wrong.
We now use the knowledge that $B_{p}$ is structurally similar to $O P T$ in order to lower bound the improvement the algorithm achieves when $p$ increases.

Lemma 15. For every $p$,

$$
\begin{aligned}
& (1-p) \cdot\left[F\left(z^{p+\delta}\left(A_{p+\delta}\right)\right)-F\left(z^{p}\left(B_{p}\right)\right)\right] \geq \\
& \quad(1-p) \delta\left(\sum_{e \in B_{p} \cap O P T} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)-\sum_{e \in \overline{B_{p}}-O P T} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)\right) \\
& \quad-p \delta\left(\sum_{e \in B_{p}-O P T} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)-\sum_{e \in \overline{B_{p} \cap O P T}} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)\right)-O\left(n^{-1} \delta\right) .
\end{aligned}
$$

Proof. Since $A_{p+\delta}=B_{p}$, the coordinate of every element of $B_{p}$ is larger in $z^{p+\delta}\left(A_{p+\delta}\right)$ by $\delta$ in comparison to its value in $z^{p}\left(B_{p}\right)$. Similarly, the elements of $\bar{B}_{p}$ are smaller by $\delta$. Hence, by Lemma 1,

$$
\begin{align*}
F\left(z^{p+\delta}\left(A_{p+\delta}\right)\right)-F\left(z^{p}\left(B_{p}\right)\right) \geq & \delta \sum_{e \in B_{p}} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)  \tag{3}\\
& -\delta \sum_{e \notin B_{p}} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)-O\left(n^{-1} \delta\right) .
\end{align*}
$$

Since $F$ is multilinear, for every element $e \in B_{p}$ with $\partial_{e} F\left(z^{p}\left(B_{p}\right)\right)<0$, removing $e$ from $B_{p}$ will increase the value of $F\left(z^{p}\left(B_{p}\right)\right)$, which contradicts our assumption that $B_{p}$ is locally optimal. Hence, for every $e \in B_{p}, \partial_{e} F\left(z^{p}\left(B_{p}\right)\right) \geq 0$. Similarly, we can also get that for every $e \notin B_{p}, \partial_{e} F\left(z^{p}\left(B_{p}\right)\right) \leq 0$. Therefore,

$$
\begin{equation*}
\sum_{e \in B_{p}-O P T} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)-\sum_{e \in \overline{B_{p} \cap O P T}} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right) \geq 0 . \tag{4}
\end{equation*}
$$

The lemma follows by multiplying (3) by $(1-p)$ and combining it with (4).

Lemma 16. For every $p$,

$$
\begin{aligned}
(1-p) \cdot\left[F\left(z^{p+\delta}\left(A_{p+\delta}\right)\right)\right. & \left.-F\left(z^{p}\left(B_{p}\right)\right)\right] \\
& \geq \delta\left[2(1-p)+(2 p-1) V\left(B_{p}\right)-2 F\left(z^{p}\left(B_{p}\right)\right)\right]
\end{aligned}
$$

Proof. Observe the following inequality.

$$
\begin{aligned}
& (1-p) \cdot\left[\sum_{e \in B_{p} \cap O P T} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)-\sum_{e \in \overline{B_{p}-O P T}} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)\right] \\
& -p\left[\sum_{e \in B_{p}-O P T} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)-\sum_{e \in \overline{B_{p} \cap O P T}} \partial_{e} F\left(z^{p}\left(B_{p}\right)\right)\right] \\
= & \sum_{e \in B_{p} \cap O P T} F\left(z^{p}\left(B_{p}\right) \cup e\right)-F\left(z^{p}\left(B_{p}\right)\right)-\sum_{e \in \overline{B_{p}-O P T}} F\left(z^{p}\left(B_{p}\right)\right)-F\left(z^{p}\left(B_{p}\right)-e\right) \\
& -\sum_{e \in B_{p}-O P T} F\left(z^{p}\left(B_{p}\right)\right)-F\left(z^{p}\left(B_{p}\right)-e\right)+\sum_{e \in \overline{B_{p} \cap O P T}} F\left(z^{p}\left(B_{p}\right) \cup e\right)-F\left(z^{p}\left(B_{p}\right)\right) \\
\geq & \left.F\left(z^{p}\left(B_{p}\right) \cup O P T\right)-F\left(z^{p}\left(B_{p}\right)\right)-F\left(z^{p}\left(B_{p}\right)\right)+F\left(z^{p}\left(B_{p}\right)-\overline{O P T}\right)\right] \\
& (*) \\
\geq & 2(1-p)+(2 p-1) V\left(B_{p}\right)-2 F\left(z^{p}\left(B_{p}\right)\right) .
\end{aligned}
$$

Where (*) follows from Theorem 1. Plugging this inequality into Lemma 15 completes the proof.

Corollary 3. For every p, $(1-p) \cdot\left[F\left(\bar{z}^{t+\delta}\left(B_{t+\delta}\right)\right)-F\left(\bar{z}^{t}\left(B_{t}\right)\right)\right] \geq \delta[1.317-$ $\left.0.634 p-2 F\left(z^{p}\left(B_{p}\right)\right)\right]-O\left(n^{-1} \delta\right)$.

Proof. Follows immediately from Lemmata 16 and 14.

Let $g$ be the function which is the solution of the following discrete recursive formula. $(1-p) \cdot[g(p+\delta)-g(p)]=\delta[(1.317-0.634 p) f(O P T)-2 g(p)]$, with the boundary condition $g(\sqrt{2} /(1+\sqrt{2}))=0.384$.

Lemma 17. For every $p, F\left(z^{p}\left(B_{p}\right)\right) \geq g(p)-O\left(p n^{-1}\right)=g(p)-O\left(n^{-1}\right)$.

Proof. Let $c$ be the constant hiding behind the big $O$ notation in Corollary 3. We prove by induction that $F\left(z^{p}\left(B_{p}\right)\right) \geq g(p)-5 c p n^{-1}$. For $p=\sqrt{2} /(1+\sqrt{2})$ the claims follows immediately from Corollary 2. Assume that the claim holds
for some $p$, let us prove it for $p+\delta$.

$$
\begin{aligned}
F\left(z^{p+\delta}\left(B_{p+\delta}\right)\right) & \geq F\left(z^{p}\left(B_{p}\right)\right)+\frac{\delta\left[1.317-0.634 p-2 F\left(z^{p}\left(B_{p}\right)\right)\right]-c n^{-1} \delta}{1-p} \\
& =F\left(z^{p}\left(B_{p}\right)\right) \cdot\left[1-\frac{2 \delta}{1-p}\right]+\frac{\delta(1.317-0.634 p)-c n^{-1} \delta}{1-p} \\
& \geq\left[g(p)-5 c p n^{-1}\right] \cdot\left[1-\frac{2 \delta}{1-p}\right]+\frac{\delta(1.317-0.634 p)-c n^{-1} \delta}{1-p} \\
& \geq g(p)+\frac{\delta[1.317-0.634 p-2 g(p)]}{1-p}-5 c(p+\delta) n^{-1} \\
& =g(p+\delta)-5 c(p+\delta) n^{-1}
\end{aligned}
$$

Let $h$ be the function:

$$
h(p)=\frac{0.0405-\frac{0.634 \sqrt{2}}{1+\sqrt{2}}}{\frac{2}{5+2 \sqrt{2}}}(1-p)^{2}+0.634(1-p)+0.3435 .
$$

Observe that $h$ if a solution of the differential equation $(1-p) \cdot \frac{d h}{d p}=1.317-$ $0.634 p-2 h(p)$. The maximum of $h$ is attained at about $p=0.752$, and $h(p)$ is monotonically increasing in the range $[\sqrt{2} /(1+\sqrt{2}), 0.752]$. Moreover, $h(0.752)>$ 0.42 , hence, it will be enough if we show that $g(p)$ is close to $h(p)$.

Lemma 18. For $p \leq 0.752, g(p) \geq h(p)$.
Proof. We prove the lemma by induction on $p$. For $p=\sqrt{2} /(1+\sqrt{2}), g(p)=h(p)$, and therefore, the lemma holds. Assume now that the lemma holds for some $p$, we will prove it for $p+\delta$. Observe the derivative of $h(p)$ is decreasing, hence,

$$
\begin{aligned}
h(p+\delta) & =h(p)+\int_{p}^{p+\delta} h^{\prime}(\rho) d \rho \leq h(p)+\int_{p}^{p+\delta} h^{\prime}(p) d \rho=h(p)+\delta \cdot h^{\prime}(p) \\
& =h(p)+\delta \cdot \frac{1.317-0.634 p-2 h(p)}{1-p} \\
& =h(p) \cdot\left(1-\frac{2 \delta}{1-p}\right)+\delta \cdot \frac{1.317-0.634 p}{1-p} \\
& \leq g(p) \cdot\left(1-\frac{2 \delta}{1-p}\right)+\delta \cdot \frac{1.317-0.634 p}{1-p}=g(p+\delta) .
\end{aligned}
$$

We are now ready to complete the proof of prove Theorem 3 by proving that our assumption that it is wrong leads to a contradiction. The value of $F\left(z^{p}\left(B_{p}\right)\right)$ at $p=0.752$ is:

$$
F\left(z^{p}\left(B_{p}\right)\right) \geq g(0.752)-O\left(n^{-1}\right) \geq h(0.752)-O\left(n^{-1}\right)>0.42 .
$$
